Electrophilic addition to olefin

ABSTRACT

The \textit{m}CPBA oxidation of methano-bridged [5,6] open fulleroid 1 anomalously resulted in the selective electrophilic addition at the bridgehead anti-Bredt double bond rather than the usual epoxidation. The mechanistic preference for the unprecedented stepwise addition of \textit{m}CPBA vs the concerted epoxidation was explained in terms of the notable \pi-orbital misalignment (>30°) based on the B3LYP/6-31G(d) level calculation.

Although fullerenes are well known as electrophiles due to the low-lying LUMO orbitals, they can also behave as nucleophiles in some chemical modifications such as epoxidation with \textit{m}-chloroperbenzoic acid (\textit{m}CPBA). The fullerene epoxides are useful reactive intermediates in the synthesis of regioselective bis-adducts and fullerene dimer. However, the control of reaction conditions to selectively give monoepoxide has been a challenging task because of the presence of a number of reactive [6,6] bonds in spherical fullerenes. In fact, the reaction of C60 with \textit{m}CPBA gives a mixture of monoepoxide and various multiepoxides, from which it is difficult to separate each of them. We are interested in the reactivity of [5,6] open fulleroid 1, with highly-twisted bridgehead double bonds as a useful synthetic entity to develop a new regioselective synthetic methodology in fullerene chemistry. Fulleroids are known as homofullerenes still retaining 60\pi-electron system and to exhibit the regioselective Zn(Cu) catalyzed hydrogenation and photooxygeination with singlet oxygen at the bridgehead olefin.

In our recent study on the comparative reactivity of the [5,6] open fulleroids vs C60, we have found the noticeably enhanced reactivity of the fulleroids at the bridgehead double bonds in Diels–Alder reaction with some flexible 1,3-dienes. It was also expected that the higher \pi-orbital misalignment angle (\textasciitilde30°), as compared to the usual anti-Bredt olefins (10–20°, vide infra), would result in a dramatic change in the reactivity mode. These situations prompted us to investigate the \textit{m}CPBA oxidation of fulleroids with the aim of bringing about the regioselective epoxidation. In this paper, we would like to report the unprecedented electrophilic addition of \textit{m}CPBA to the anti-Bredt olefin of the fulleroid 1 as shown in Scheme 1 and discuss the mechanistic feature on the basis of the B3LYP/6-31G(d) calculation.

\textit{m}CPBA oxidation of methano-bridged 1, with \textit{m}CPBA (10 equiv.) at 30 °C gave several oxidized products, as seen in the HPLC chart of the reaction mixture (Figure 1a). The APCI-LCMS measurement showed the sharp peak of the residual 1 along with the following broad peak consisting of a mixture of 1:1 adduct (1+\textit{m}CPBA: m/z = 906) and its fragment (m/z = 751, 1+OH +) (Figure 1b). preceding shoulder fraction overlapped with 1 seems to be monoepoxide (m/z = 922) of the 1:1 adduct and its fragment (m/z = 767) (Figure 1c).

Figure 1. (a) HPLC chart for mCPBA oxidation of 1 (after 6h) and APCI-MS (positive) of (b) 2a+2b and (c) byproduct.

The portion of 1:1 adduct was successfully fractionated by silica gel column chromatography (15.4 mg; 15% isolated yield). The purity was verified by HPLC (Figure S1). The isolated product showed the characteristic IR absorption at 1727 cm$^{-1}$ assignable to the benzoate ester group. Unfortunately, this fraction was still the regioisomeric mixture (major/minor = 3) of 1:1 adducts 2a/2b by $^1$H NMR spectrum (Figure 2). Although an attempt to separate and assign these region-isomers was failed, we tentatively assign 2a to the major isomer according to the calculation (vide infra). However, the 1,2-addition at the bridgehead double bond was undoubtedly evidenced by the following facts. (1) The significant down-field shift (1.6–2.3 ppm) of the methano-bridged H(b) was found for the major ($\delta$ = 5.2 ppm, Figure S2) and for the minor (4.5), respectively, as compared to that of parent 1 (2.9). These shifts were clearly explained by the reduction of the shielding effects of underlying hexagonal triene ring by 1,2-addition of mCPBA. (2) The 2D HMBC correlation is observed (Figure S3) between each of the bridged H(a)/H(b) and the OH or m-chlorobenzoate (mCB)-substituted remote sp$^3$-carbon (C$_{\beta}$, red circle). (3) The existence of NOE interaction between the hydroxy proton H(g) and the magnetically isolated o-proton H(f) would support the formation of 1,2-adducts (Figure S4). However, there is no NOE enhancement between the bridged CH$_2$ and any proton of the mCB group, indicating the less congested outward orientation of mCB moiety.

This electrophilic esterification of fulleroid by mCPBA is unprecedented and markedly contrast to the usual epoxidation of C$_{60}$ as well as the common olefins. It is likely that the highly twisted double bond of 1 plays a crucial role in the present 1,2-addition of mCPBA. Then, we calculated its transition state (TS) and intrinsic reaction coordinate (IRC) with B3LYP/6-31G(d) level (Figure 3) in order to gain a mechanistic insight into the mCPBA oxidation of 1. The results showed the asymmetric transition state TS-1 (Figure 3a) in which the relevant OH group is located more closer to the bridgehead C$_{\alpha}$ than to the adjacent C$_{\beta}$ carbon and then leads to the ionic intermediate 1aOH$^+$ (Figure 3b). On the other hand, the asymmetric approach of mCPBA to the C$_{\beta}$ carbon would generate the energetically higher transition state TS-2 and provide the less stable intermediate 1bOH$^+$ (Figure 3c,d), in conformity with the minor 2b. Although the energy difference (3.8 kcal/mol) between TS-1 and TS-2 is larger than the value deduced from the experimental product ratio (3:1), this may be ascribed to the several reasons. The appreciable difference in HOMO orbital coefficients of the anti-Bredt double
bond moiety is also likely responsible for such an asymmetric electrophilic attack (Figure S6). These two pathways can be terminologically categorized as bimolecular electrophilic addition (AdE-).

To verify whether the present calculations are reasonable, we have compared our results with those of the previously reported mCPBA oxidation of olefins.\textsuperscript{19,21} Though the reported studies have mainly concerns the simple and less twisted alkenes, two reaction pathways have been proposed; one is the generally accepted concerted process via a butterfly-like symmetrical transition state (route (a) in Scheme 2)\textsuperscript{19} and another is the stepwise process via asymmetric transition state and the ionic intermediate,\textsuperscript{20} similar to the present calculation (route (b) in Scheme 2). While the higher level calculations\textsuperscript{19a} and the detailed investigation of isotope effect\textsuperscript{19c,21} supported the concerted mechanism, our results indicated that twisted olefin prefers the route (b),\textsuperscript{22} probably because the highly twisted π-orbital could not perform the symmetrical orbital interaction with mCPBA as in route (a). The generated intermediate 1aOH\textsuperscript{1} undergoes the addition of m-chlorobenzoate (mCB\textsuperscript{1}), rather than the ring-closure to epoxide. Indeed, the intervention of such intermediate was proved by formation of the crossover p-methyl benzoate adduct (m/z = 886) when m-toluic acid coexists (route (c) in Scheme 2 and Figure S7).

**Figure 3.** Relative energy vs the reaction coordinate (translated to the distance between C\textsubscript{B} or C\textsubscript{C} and O\textsubscript{mp}, for TS-1 or TS-2, respectively, obtained from TS and IRC calculations. (a) Geometry of the TS-1 of 1 + mCPBA reaction (Imaginary freq. = 104 cm\textsuperscript{-1}, dipole moment (µ = 3.6 D). (b) Geometry of the 1aOH\textsuperscript{1} and m-chlorobenzoate (mCB\textsuperscript{1}) obtained from the IRC calculation (not optimized structure).\textsuperscript{17} (c) Geometry of the TS-2 of 1 + mCPBA reaction (Imaginary freq. = 249 cm\textsuperscript{-1}, µ = 5.4 D). (d) Geometry of the 1bOH\textsuperscript{1} and m-chlorobenzoate (mCB\textsuperscript{1}) obtained from the IRC calculation (not optimized structure).\textsuperscript{17} These geometries and energies were calculated by B3LYP/6-31G(d) level without solvation parameter. The yellow balls denote the cycloheptatriene ring.

One question is raised why mCPBA oxidation of several anti-Bredt olefins\textsuperscript{23} exclusively gave the epoxides. The π-orbital misalignment angle τ (15.7º for bicyclo[3.3.1]nonane, calculated by B3LYP/6-31G*) is considerably smaller than those of the fulleroids (>30º).\textsuperscript{8,10} The calculation for the bicyclic compound provided rather symmetrical TS (Figure S8) in accord with the actual epoxidation, implying that even anti-Bredt olefins allow the symmetric TS via route (a), when τ is not so large.

In conclusion, we have found that the methano-bridged [5,6] open fulleroxin was underwent the stepwise bimolecular electrophilic addition (AdE\textsuperscript{2}) of mCPBA at the twisted bridgehead double bond to afford the regiosomeric mixture of α-hydroxyfullerene m-chlorobenzoates. This unusual addition was rationalized by the larger torsional angle of double bond (τ ~ 30º), which would inhibit the symmetric TS (so-called butterfly TS) generally argued for the concerted epoxidation of olefins.

26. Although our calculational method (DFT/B3LYP) is relatively rough as compared to the previous theoretical calculations (such as QCISD in ref. 19a), these higher calculations cannot be straightforwardly applied to fulleroid with too many atoms and electrons. Multi-layered method such as ONIOM will enable such higher level calculation to fulleroid, as the following recent ONIOM application to the Diels–Alder reaction of fullerene.
