For the first time, we obtained the $g$ factor for the ground state of $^{23}\text{Al}$ by use of a $\beta$-NMR measurement. $^{23}\text{Al}$ has a small proton separation energy and is a potential proton-halo candidate. The obtained $g$ factor, $|g| = 1.557 \pm 0.088$, clearly shows the spin and parity, $J^\pi = 5/2^+$, for $^{23}\text{Al}$, which is the same as that of its mirror partner, $^{23}\text{Ne}$. The possible nuclear structure of $^{23}\text{Al}$ is also discussed.

Studies of exotic nuclei far from the stability line have attracted much interest during the past two decades since the first observation of the neutron halo in $^{11}\text{Li}$ [1]. Further experiments have confirmed the neutron halo in $^{11}\text{Li}$, and have also shown the existence of a neutron halo in other neutron-rich nuclei [2]. However, the number of experiments on the proton halo are relatively few compared with those on the neutron halo. Recently, experimental evidence for the proton halo in very proton-rich nuclei has become available: $^{8}\text{B}$ [3–5], $^{17}\text{Ne}$ [6,7], and $^{26,27,28}\text{P}$ [8]. $^{23}\text{Al}$ is one of the potential candidates for a proton-halo nucleus, because its proton separation energy is quite small (125 keV). Recently, a large research cross section of $^{23}\text{Al}$ was measured at the intermediate energy (∼36 MeV), although the error was still large [9,10]. The authors of Ref. [9,10] analyzed the data by a Glauber model with simply a core nucleus ($^{22}\text{Mg}$) plus a valence proton ($p$) configuration. According to their analysis, the density distribution of $^{23}\text{Al}$ should have a halolike long tail. Because the density of a loosely bound s-wave proton can be extended, it is suggested that the spin and parity ($J^\pi$) of $^{23}\text{Al}$ might be $1/2^+$. However, the $J^\pi$ of its mirror partner, $^{23}\text{Ne}$, is $5/2^+$. Thus, if the ground-state $J^\pi$ of $^{23}\text{Al}$ is $1/2^+$, the proton halo structure can be anticipated, but the mirror symmetry will be broken between the bound ground states of mirror pairs, which has not been observed for known nuclei so far. Because the magnetic moment of its mirror partner, $^{23}\text{Ne}$, is known to be $-1.077 \pm 0.004$ [11], the magnetic moment of $^{23}\text{Al}$ allows one to discuss the spin expectation value [12] of the $A = 23$ mirror pair with $T = 3/2$, where $T$ is the isobaric spin. In p-shell nuclei, the $^9\text{C}$–$^{14}\text{Li}$ mirror moments ($T = 3/2$) yield an anomalous large spin expectation value, which suggests an exotic structure of proton-rich $^9\text{C}$ [13]. A similar anomaly may be found in the sd-shell region.

Determining the ground-state $J^\pi$ of $^{23}\text{Al}$ is also important from a nuclear astrophysical aspect. The $^{22}\text{Mg}(p,\gamma)^{23}\text{Al}$ reaction is relevant to the nucleosynthesis of $^{22}\text{Na}$ in Ne-rich novae [14]. The $^{22}\text{Na}$ yield might be reduced if an escape from the reaction sequence takes place via the $^{22}\text{Mg}(p,\gamma)^{23}\text{Al}$ reaction. In novae, resonant capture through the first excited state contributes dominantly, because the first excited state of $^{23}\text{Al}$, lying at 405 keV above the proton threshold, locates near the Gamow energy. To calculate the strength of the resonant capture, determining the spin of the first excited state of $^{23}\text{Al}$ is necessary [15]. In the previous works [16,17], $J^\pi = 1/2^+$ is suggested for the first excited state, which implies $J^\pi = 5/2^+$ for the ground state. Thus, if the ground-state $J^\pi$ is $5/2^+$, the suggestions by the previous works will be supported.

Until now, there has been no direct measurement for $J^\pi$ of $^{23}\text{Al}$. The $\beta$-decay of $^{23}\text{Al}$ to excited states in $^{23}\text{Mg}$ has been investigated [18]. Although the $\beta$-decay branching ratio to the ground state ($J^\pi = 3/2^+$) of $^{23}\text{Mg}$ has not been measured, the strength of $\beta$-decay branches to the excited states in $^{23}\text{Mg}$ strongly suggested $J^\pi = 5/2^+$ for the ground state of $^{23}\text{Al}$. The magnetic moment allows us to determine the spin and parity directly, because the magnetic moment is very different for the different spin [19]. Therefore, we measured the magnetic moment of $^{23}\text{Al}$.

The $^{22}\text{Al}$ nuclei were produced through the projectile-fragmentation process in the collision of $^{28}\text{Si}$ on a $^9\text{Be}$ target, as the RI beam. The primary beam of $^{28}\text{Si}$ was accelerated up to 135 A MeV by the RIKEN ring cyclotron. The Be target thickness was 4.0 mm. Only the fragments ejected at angles of
1.0°±0.6° were separated by the fragment separator, RIPS. In the separator, the momentum of the fragments was analyzed, and only the fragments with a momentum 2.0±0.5% larger than the central momentum were selected. The projectile fragments were polarized with this selection of the reaction angle and the momentum [20]. The major contaminants in the RI beam were isotones of 23Al: 22Mg, 21Na, and so on. To sweep the isotones of 23Al was detected by the catcher of 0.6 mm in thickness placed in a strong magnetic field, which was separated by the fragment separator, RIPS. In the first measurement, the space from the final energy degrader to the catcher was in a vacuum so as to completely remove any polarization destruction by gas collisions before the catcher. Preliminary results of the first measurement are shown in Ref. [23].

A NMR spectrum for wide frequency modulation (FM) of ±500 kHz is shown in the upper part of Fig. 3. The data were averaged by the first and the second measurements. We found a resonance at around 3600 kHz. To determine the resonance more precisely, we performed measurements with a narrow FM of ±200 kHz. The obtained NMR spectra are shown in the lower part of Fig. 3. For fitting the NMR spectrum, we took into account the width of the FM and the strength of the magnetic fields. The fitting function, \( S(\omega) \), is given by

\[
S(\omega) = \frac{1 - \cos \alpha(\omega) \cdot \cos \beta(\omega)}{2} A P,
\]

where \( A \) is the \( \beta \)-decay asymmetry parameter and \( P \) is the spin polarization. The \( \alpha(\omega) \) and \( \beta(\omega) \) are defined by the direction to the entrance of the catcher chamber was filled with He gas. In the second measurement, the whole region from the final energy degrader to the catcher was in a vacuum so as to completely remove any polarization destruction by gas collisions before the catcher. Preliminary results of the first measurement are shown in Ref. [23].

We performed two measurements with different setups. In the first measurement, the space from the final energy degrader...
of the nuclear spin at the start of FM and the end of FM to the 
\( H_0 \), as given by

\[
\cot \alpha(\omega) = \frac{\omega_0 - (\omega - \omega_{\text{FM}})}{\omega_1}
\]

and

\[
\cot \beta(\omega) = \frac{\omega_0 - (\omega + \omega_{\text{FM}})}{\omega_1},
\]

where \( \omega_0 = g \mu_N H_0 / \hbar \) is the Larmor frequency, \( \omega_1 = g \mu_N H_1 / \hbar \), and \( \omega_{\text{FM}} \) is the half-width of the FM. The fitting results are shown by the lines in Fig. 3. The resonance frequency was determined to be 3558.8±15.8 (statistical) ±200 (systematical) kHz. It is noted that the statistical error was determined by the average of the data with a wide and narrow FM, and the systematical errors were simply weighted. We took into account a small diamagnetic correction (8.3

and parity of \(^{23}\text{Al}\). We used the OXBASH code with the

configuration of case (i) is 71%, that of case (ii) is only 0.2%, and that of case (iii) is 23%. It is noted that, in the mirror partner \(^{23}\text{Ne}\), the \( d\)-wave valence neutron is dominant in the ground state, which was shown by the \(^{23}\text{Ne}(d,p)^{24}\text{Ne}\) reactions [26]. Thus, the configuration with the \( d\)-wave valence proton is the most probable for \(^{23}\text{Al}\).

It is noted how the authors concluded the proton halo structure for \(^{23}\text{Al}\). They measured reaction cross sections of \(^{23}\text{Al}\) and \(^{22}\text{Mg}\) at ~36.4 MeV and found a much larger reaction cross section for \(^{23}\text{Al}\) than for \(^{22}\text{Mg}\). To reproduce the enhancement by the simple \(^{22}\text{Mg}+p\) configuration based on the Glauber model, the halolike tail is needed for \(^{23}\text{Al}\). Loosely bound \( s\)-wave protons can extend its density so much because of no centrifugal barrier \((l = 0)\) [27]. Thus the authors of Refs. [9,10] concluded \( J^\pi = 1/2^+ \) for \(^{23}\text{Al}\). However, if the \( J^\pi \) of \(^{23}\text{Al}\) is \( 5/2^+ \), the \( d\)-wave proton is dominant, as discussed above. Thus, the large reaction cross section of \(^{23}\text{Al}\) compared to that of \(^{22}\text{Mg}\) cannot be explained by the simple \(^{22}\text{Mg}+p\) configuration based on the Glauber model. A similar puzzle is also observed in \(^{19}\text{C}\) and \(^{21}\text{O}\). In both nuclei, large interaction cross sections cannot be reproduced by the simple core-\(n\)-neutron configuration, even for the pure \( s\)-wave valence neutron [28,29]. One solution may be to introduce a core modification [30]. Although the core-\(p\)-valence nucleon structure is fulfilled, the density of the core nucleus is much larger than that in the free space. Thus, the large reaction-interaction cross sections of these nuclei are because of the large density of the core. The spin expectation value can be determined from the present result combined with the magnetic moment of the mirror partner, \(^{23}\text{Ne}\). For the calculation, the sign of the magnetic moment of \(^{23}\text{Al}\) was assumed to be positive, which is predicted by our shell-model calculation. Thus, the spin expectation value was determined to be \(+0.8\pm0.6\). The present error is still large for further discussion about detailed configuration mixing of the nucleus. Experimental results of magnetic moments of the mirror pair with \( T = 3/2 \) nearby \(^{23}\text{Ne}\) are noted. Very recently, magnetic moments of \(^{17}\text{Ne}\) [11] and \(^{35}\text{K}\) [31] have been measured. Thus, the mirror pair with \( T = 3/2 \) for \( A = 17 \) and \( A = 35 \) can be discussed. For both systems, no anomalous spin expectation values have not been observed. For \( A = 21 \) and \( A = 25 \), magnetic moments of neutron rich nuclei \(^{21}\text{F}\) and \(^{27}\text{Na}\) are experimentally known [32]. Thus, if we measure the magnetic moments of
$^{21}\text{Mg}\left(J^\pi = 5/2^+\right)$ and $^{25}\text{Si}\left(J^\pi = 5/2^+\right)$, the spin expectation value can be extracted.

For $^{23}\text{Al}$, one unbound excited state with $E_x = 528$ keV is known, as shown in Fig. 4. Our shell-model calculation shows that $J^\pi$ of the first excited state is $1/2^+$ if the ground state of $^{23}\text{Al}$ is $J^\pi = 5/2^+$. These assignments are important to estimate the strength of the resonant capture in the $^{22}\text{Mg}\left(p, \gamma\right)^{23}\text{Al}$ reaction.

In summary, the $g$ factor of the ground state of $^{23}\text{Al}$, which is a potential proton-halo candidate, has been measured for the first time. The obtained $|g| = 1.557 \pm 0.088$ clearly shows the spin and parity $J^\pi = 5/2^+$ for $^{23}\text{Al}$, which was strongly suggested by the previous $\beta$-decay measurement [18]. Thus, the mirror symmetry is fulfilled in the ground states between $^{23}\text{Al}$ and $^{23}\text{Ne}$. Determining the spin and parity provides a strong restriction to the possible nuclear structure of $^{23}\text{Al}$. If we assume a simple $^{22}\text{Mg} + p$ structure for $^{23}\text{Al}$, a configuration, including the $d$-wave valence proton, is most probable for $^{23}\text{Al}$. However, previously observed large reaction cross section of the nucleus at the intermediate energy ($\sim 36\text{A MeV}$) cannot be reproduced well. Experimentally, more reliable and accurate measurements of the reaction cross sections are urged with different energies. Energy dependences of the reaction cross sections can describe effective matter densities of $^{23}\text{Al}$ in detail [4]. Concerning a possible proton halo structure of $^{23}\text{Al}$, measurements of the momentum distribution of fragments from $^{23}\text{Al}$ and the quadrupole moment of $^{23}\text{Al}$ will give more information. The present result on the ground state spin and parity may remove any uncertainty in estimating the strength of the resonant capture cross section of $^{22}\text{Mg}\left(p, \gamma\right)^{23}\text{Al}$. Previously, the ground state of $J^\pi = 5/2^+$ and the first excited state of $J^\pi = 1/2^+$ in $^{23}\text{Al}$ were assumed [15]. The present measurements show that the above spin assignments are proper.

The present work was performed at the RIKEN Ring Cyclotron. The authors are grateful to the staff of RIKEN for their technical support. Support was also given by a grant-in-aid for Scientific Research from the Ministry of Education, Culture and Science, Japan.
