Iterative Algorithm for Reducing the Peak-to-Average Power Ratio of Feedback-Controlled Multitone-Hopping CDMA Signals

Kazuki CHIBA$^{(a)}$, Student Member and Masanori HAMAMURA$^*$, Member

SUMMARY A novel peak-to-average power ratio (PAR) control algorithm for feedback-controlled multitone-hopping code-division multiple access (FC/MH-CDMA) signals is proposed. In FC/MH-CDMA, since each chip consists of plural tones, the energy consumption due to a large PAR is not negligible at the transmitter. The proposed PAR control algorithm iteratively constructs a time-frequency code that achieves a preset, target PAR under the condition that all signals are asynchronously transmitted. A PAR of 1 dB is shown to be achievable, and the bit-error rate performance is shown to be only slightly influenced if the target PAR is set to be larger than 3 dB. The influence of quantization is also discussed in terms of its application to limited feedback channels.

key words: CDMA, asynchronous, multipath, feedback, multitone, PAR

1. Introduction

Intersymbol interference (ISI) and multiple access interference (MAI) are two primary causes of the deterioration of wireless communication performance [1]–[4]. Feedback-based systems have been investigated in an attempt to greatly reduce ISI and MAI [5]. For uplink channels, a method in which a base station (BS) uses an adaptive filter at a receiver to produce an analog pseudo-noise (PN) sequence, which is assigned to a new user, was proposed [6] in the context of direct-sequence code-division multiple access (DS-CDMA). Analog PN sequences can be orthogonal to each other under arbitrary asynchronous conditions. For synchronous DS-CDMA, an iterative construction method that produces signature sequences using a minimum mean-squared error (MMSE) filter was proposed [7]. This method was demonstrated to produce a set of Welch bound equality (WBE) sequences [8], [9] using an MMSE filter, the size of which is identical to the length of the signature sequence. In contrast, we previously proposed feedback-controlled DS-CDMA (FC/DS-CDMA) [10], in which the receiver uses an adaptive filter that is larger than the length of the signature sequence and returns part of the filter coefficients to the transmitter. This method has been shown to have superior performance in terms of bit-error rate (BER) over time-invariant multipath channels. Furthermore, we proposed feedback-controlled multitone-hopping CDMA (FC/MH-CDMA), which combines frequency-hopping CDMA (FH-CDMA) with FC/DS-CDMA, to increase the signal-to-interference plus noise ratio (SINR) [11]. Each receiver of FC/MH-CDMA is composed of a time-frequency, two-dimensional, adaptive finite-duration impulse response (FIR) filter, which is larger than the hopping pattern. The receiver returns part of the filter coefficients to the transmitter. The signals transmitted in FC/MH-CDMA consist of coded multiple-frequency tones.

In order to address the large peak-to-average power ratio (PAR) of multicarrier signals, which results in increased energy consumption at the transmitter, PAR reduction techniques have been discussed. Clipping is one of the easiest PAR reduction methods [12]. When the amplitude of multicarrier signals exceeds the threshold, clipping replaces the amplitude with the threshold level. In the selected mapping [13], the transmitter generates plural multicarrier signals that have the same message symbols with independent phase rotation, and the transmitter selects a signal that minimizes the PAR in the plural multicarrier signals. Using block codes, the PAR of multicarrier signals can be reduced [14], [15]. For example, the multicarrier signals using Golay complementary sequences limit the value of the PAR at 3 dB. Recently, on the other hand, DS-CDMA has also been reconsidered for the applications of synchronous or quasi-synchronous uplink channels [16] because of its small PAR [17].

Typically, since the performance, such as the BER and/or user capacity, of multicarrier signals is deteriorated by such a PAR reduction technique, it is of extreme importance for FC/MH-CDMA to find a PAR reduction technique that has minimal impact on the BER and user capacity, even for asynchronous multiple access. Previously, we investigated the PAR of FC/MH-CDMA signals and showed that several techniques, such as tone selection by limiting the number of tones per chip, quantization for reducing the overhead for feedback, and clipping the time-frequency code, are effective for reducing the PAR by a few dB at an almost identical BER [18].

In this paper, we propose a PAR reduction algorithm...

for FC/MH-CDMA signals, which controls the PAR to a preset target value with good BER performance over asynchronous and time-invariant multipath channels.

The remainder of this paper is organized as follows. FC/MH-CDMA is introduced in Sect. 2. In Sect. 3, an iterative PAR control algorithm for reducing the PAR of FC/MH-CDMA signals is presented. The effectiveness of the proposed algorithm is verified in Sect. 4.

2. FC/MH-CDMA

2.1 Transmitter

We assume the uplink multiple access shown in Fig. 1. A signal received at the position of BS can be modeled as the sum of $K$ signals that are independently transmitted through distinct channels. The transmitter and receiver for the $k$th signal ($k = 1, 2, \cdots, K$) of FC/MH-CDMA are shown in Fig. 2.

The signature waveform $c_k(t)$ for the $k$th signal is given by

$$c_k(t) = \sum_{l=1}^{L} a_{k,l}(t - (l - 1)T_c),$$  (1)

where $a_{k,l}(t)(0 < t < T_c; T_c[k] is the chip duration)$ is the $l$th chip waveform ($l = 1, 2, \cdots, L; L$ is the number of chips) for $c_k(t)$, which is given by

$$a_{k,l}(t) = g(t)\sum_{m=1}^{M} p_{k,l,m}e^{j2\pi j\tau_{k,l,m}/T_s},$$  (2)

where $j = \sqrt{-1}$, $p_{k,l,m}$ is the complex amplitude of the $m$th tone of frequency $\frac{f_k}{T_s}$ [Hz] ($m = 1, 2, \cdots, M; M$ is the number of transmittable tones per chip) for the $l$th chip of $c_k(t)$, and $g(t) = \{1(0 < t < T_c), 0(\text{otherwise})\}$.

Let $P_k$ be an $L \times M$ matrix that contains $p_{k,l,m}$ such that

$$P_k = \begin{bmatrix}
    p_{k,l,1} & p_{k,1,2} & \cdots & p_{k,1,M} \\
    p_{k,2,1} & p_{k,2,2} & \cdots & p_{k,2,M} \\
    \vdots & \vdots & \ddots & \vdots \\
    p_{k,L,1} & p_{k,L,2} & \cdots & p_{k,L,M}
\end{bmatrix}.  (3)$$

The matrix $P_k$ is referred to as the hopping pattern or time-frequency code for the $k$th signal.

The $k$th signal transmitted by the transmitter is given by

$$s_k(t) = \sum_{n=0}^{\infty} b_k(n)c_k(t - nT_s),$$  (4)

where $b_k(n)$ is a complex message symbol transmitted in $nT_s < t < (n + 1)T_s$ ($n = 0, 1, \cdots$), and $T_s[k]$ is the symbol duration ($T_s = LT_c$). In this paper, we assume that $b_k(n)$ is a quaternary phase-shift keying (QPSK) symbol.

2.2 Channel

Let $h_k(t)$ be the impulse response of the channel through which the $k$th signal ($k = 1, 2, \cdots, K$) is transmitted to the BS, as given by

$$h_k(t) = \sum_{l=1}^{I_k} h_{k,l}d(t - \tau_{k,l}),$$  (5)

where $h_{k,l} = |h_{k,l}|e^{j\theta_{k,l}}$ is the complex gain constant for the $l$th path of the channel, $\tau_{k,l} (0 \leq \tau_{k,l} < T_s)$ is the delay for the $l$th path, and $I_k$ is the number of paths of the channel.

The received signal $r(t)$ at the position of the BS is given by

$$r(t) = \sum_{k=1}^{K} \sum_{n=0}^{\infty} \sum_{l=1}^{I_k} h_{k,l}b_k(n)c_k(t - nT_s - \tau_{k,l}) + n(t),$$  (6)

where $n(t)$ is an additive white Gaussian noise (AWGN) with a double-sided power spectral density of $N_0/2$ [W/Hz].

2.3 Receiver

The receiver for the $k$th signal is composed of the adaptive FIR filter and operates symbol-by-symbol. The FIR filter has $(L + \alpha) \times M$ complex weights ($0 \leq \alpha \leq L$), which are used for recovering the message symbol $b_k(n)$ while reducing ISI and MAI. In FC/MH-CDMA, the receiver filter is larger than the hopping pattern $P_k$, as shown in Fig. 2, to fully collect the received, time-spread energy over the multipath channel and to produce an updated hopping pattern that efficiently achieves a smaller BER [10], [11]. Let $W_k$ be an $(L + \alpha) \times M$ matrix, the $(l,m)$th entry of which is the complex weight $w_{k,l,m}$ of the receiver. The weight matrix $W_k$ is updated by an adaptive algorithm. In this paper, we adopt a normalized least-mean-square (N-LMS) algorithm [19], which is one of the less complex adaptation algorithms. For simplicity, the receiver for the $k$th signal is assumed to be synchronized with the first path of the channel $h_{k,1}(t)$.

The $k$th receiver obtains discrete-time samples of every frequency and chip from the received signal $r_k(t)$. The $m$th frequency component $r_{k,l,m}$, detected at $t = nT_s + lT_s + \tau_{k,l,1}$ ($l = 1, 2, \cdots, L + \alpha$), is given by
where the superscript $H$ is defined as matrix.

\[ \hat{W}_k(n) = \text{tr}[\mathbf{W}_k^H(n) \mathbf{R}_k(n)] \]

The FIR filter output $\hat{b}_k(n)$ can be represented as

\[ \hat{b}_k(n) = \text{tr}[\mathbf{W}_k^H(n) \mathbf{R}_k(n)] \]

where the superscript $^H$ denotes the complex conjugate and transpose of the matrix, and \(\text{tr}[\cdot]\) denotes the trace of the matrix.

The weight matrix $\mathbf{W}_k(n)$ is updated as

\[ \mathbf{W}_k(n+1) = \mathbf{W}_k(n) + \frac{\mu \mathbf{R}_k(n) e_k(n)}{||\mathbf{R}_k(n)||_F^2} \]

where $\mu$ is the step size parameter, and $||\mathbf{R}_k(n)||_F$ denotes the Frobenius norm of the received signal matrix $\mathbf{R}_k(n)$, which is defined as

\[ ||\mathbf{R}_k(n)||_F = \sqrt{\sum_{l=1}^{L \times T_f} \sum_{m=1}^M |r_{k,l,m}(n)|^2} \]

In addition, the superscript $^*$ denotes the complex conjugate, and $e_k(n)$ is given as

\[ e_k(n) = \hat{b}_k(n) - \text{tr}[\mathbf{W}_k^H(n) \mathbf{R}_k(n)], \]

where

\[ \hat{b}_k(n) = \text{sgn}[\text{Re}[\hat{b}_k(n)]] + j\text{sgn}[\text{Im}[\hat{b}_k(n)]] \]

Here, \(\text{sgn}[-]\) is the signum function, \(\text{Re}[-]\) is the real part of the complex value, and \(\text{Im}[-]\) is the imaginary part of the complex value.

In this paper, the initial value $\mathbf{W}_k(0)$ of the weight matrix $\mathbf{W}_k(n)$ for the $k$th receiver is chosen to be a set of weights that consists of the corresponding initial hopping pattern $\mathbf{P}_k(0)$ and the zero matrix $\mathbf{0}_{M \times M}$ of size $\alpha \times M$, that is,

\[ \mathbf{W}_k(0) = [\mathbf{P}_k^T(0) \ 0^{T \times M}]^T \]

where the superscript $^T$ denotes the transpose of the matrix.

2.4 Feedback

Part of the FIR filter weights of the receiver for the $k$th signal are fed back to the corresponding transmitter, in which they are used as an updated version of the hopping pattern $\mathbf{P}_k$. When no delay time and no error for the feedback are assumed, the hopping pattern $\mathbf{P}_k(\lambda)$ updated at

\[ t = nT_f + (L + \alpha)T_e + \tau_{k,1} \]

is the preassigned offset of the feedback timing ($0 \leq \Delta_k < T_f$) is represented as
where \( \hat{n}_k \triangleq [(\lambda T_f + \Delta_k + \alpha T_c + \tau_{k,1})/T_c] \), and \([ \cdot ]\) is the largest integer that is less than or equal to the operand.

Equations (16) and (17) intend that the value of each element \( p_{k,l,m} \) of the hopping pattern is replaced with the value of each element \( w_{k,l,m} \) of part of the FIR filter weights at \( t = \lambda T_f + \Delta_k + \alpha T_c + \tau_{k,1} \).

Although the updated hopping pattern is fed back to the corresponding transmitter, as in [11], \( P_{k}(\lambda) \) is altered to obtain a different hopping pattern \( \hat{P}_k(\lambda) \) using the PAR control algorithm described in the following section. Furthermore, when the influence of quantization is considered, \( P_k^*(\lambda) \) is again altered to obtain \( P_k^*(\lambda) \).

3. PAR Control and Quantization

3.1 Proposed Algorithm for PAR Control

Since the updated hopping pattern \( P_k(\lambda) \) is constructed at the receiver, the receiver can reconstruct the updated hopping pattern to control the PAR of the signature waveform \( c_k(t) \) to be a small target value \( PAR \), of the PAR. In this paper, we define the PAR of the signature waveform \( c_k(t) \) as

\[
PAR = \frac{\max_{0 \leq t < T_c} |c_k(t)|^2}{1/T_c \int_0^{T_c} |c_k(t)|^2 \, dt}.
\]

(18)

Once a hopping pattern \( P_k(\lambda) \) is given, \( c_k(t) \) is readily obtained using (1) and (2).

One of the optimum hopping patterns that minimizes the value of the PAR is a hopping pattern \( P_k(\lambda) \), each row of which contains only one nonzero element having a constant absolute value. This type of hopping pattern yields a signature waveform, each chip of which consists of a single tone having a constant amplitude level, resulting in a minimum value of PAR of 0 dB, because of its constant modulus. Although such a hopping pattern can easily be constructed, it causes severe MAI, especially in wireless asynchronous and multipath environments.

Although the basic concept underlying the proposed algorithm is to construct such a hopping pattern to control the PAR, the proposed algorithm is an attempt to gradually bring \( P_k(\lambda) \) up to such a hopping pattern without the occurrence of MAI in multipath environments with the help of the feedback mechanism in FC/MH-CDMA. Since all K receivers use the proposed algorithm independently, the proposed algorithm is directly applied for decentralized multiple access where no BS exists.

Our algorithm is based on the following considerations. To reduce the value of the PAR of the signature waveform, the chip that has the largest amplitude level must be small. Since FC/MH-CDMA produces a set of signature waveforms, or equivalently, a set of hopping patterns that achieves the highest SINR, the elements (not the chip) that have large amplitudes contained in such a hopping pattern are important for obtaining a high SINR, and conversely, the elements that have small amplitudes are not important for obtaining a high SINR. Therefore, the tone with the smallest amplitude contained in the chip with the largest amplitude can be reduced to obtain a low PAR signal with minimal impact on the SINR. Next, we describe in detail the PAR control algorithm, which is also summarized in Fig. 3. The PAR control algorithm has two design parameters \( \beta \) and \( \rho \) in addition to the target value \( PAR \) of the PAR. Basically, the value of \( \beta \) is chosen to be smaller and \( \rho \) is chosen to be greater if a small PAR is required, and vice versa. The impacts of the values of these parameters on the achievable PAR and computational complexity are elaborated through simulations in Sect. 4.2.1.

1) Construct an \( L \times M \) matrix \( \hat{P}_k(\lambda) = [\hat{p}_{k,l,m}(\lambda)] \) using \( P_k(\lambda) \) such that

Fig. 3 Flowchart of the PAR control algorithm.
\[ \hat{p}_{k,l,m} = \begin{cases} 0 & (|p_{k,l,m}| < \gamma) \\ p_{k,l,m} & (|p_{k,l,m}| \geq \gamma) \end{cases}, \]

where \( \gamma \) is the threshold level used to reduce the number of tones and is defined as

\[ \gamma = \beta \sqrt{\frac{1}{LM} \| P_{k}(\lambda) \|^2_{\text{F}}} \]

where \( \beta (>0) \) is a positive real constant that represents the threshold level normalized to the root mean squared value \( \sqrt{\frac{1}{LM} \| P_{k}(\lambda) \|^2_{\text{F}}} \) of the elements of \( P_{k}(\lambda) \).

We assume that \( N_{t} (0 \leq N_{t} \leq M, l = 1, 2, \cdots, L) \) is the number of nonzero elements contained in the \( l \)th row of the matrix \( P_{k}(\lambda) \).

2) Calculate the value \( \xi_{k} \) of the PAR for the signature waveform \( \hat{c}_{k}(t) \) obtained using the matrix \( P_{k}(\lambda) \) and compare \( \xi_{k} \) with the target value \( \text{PAR} \), of the PAR.

3) If \( \xi_{k} \leq 	ext{PAR} \), or if \( N_{t} \leq 1 \) for all \( l \), then the matrix \( \hat{P}_{k}(\lambda) \) can be used as \( P_{k}(\lambda) \) for the feedback to the transmitter.

4) If \( \xi_{k} > \text{PAR} \), and if \( N_{t} > 1 \) for one of the \( L \) values of \( N_{t} \), then find a tone index \( \hat{m} \) \((1 \leq \hat{m} \leq M)\), which indicates that the \( \hat{m} \)th chip has the largest value of \( |\lambda^{k}_{\hat{m}}(t)| \), and find a tone index \( \tilde{m} \) \((1 \leq \tilde{m} \leq M)\), which indicates that the absolute value \( |\lambda^{k}_{\tilde{m}}(\lambda)| \) of the \( \tilde{m} \)th tone in the \( \hat{m} \)th chip is the smallest nonzero value, and then change the value of \( p_{k,l,m}(\lambda) \) to a smaller value \( \rho \cdot \hat{p}_{k,l,m}(\lambda) \) by a factor of \( 0 < \rho < 1 \), where the factor \( \rho \) corresponds to the sensitivity for reducing the value of the PAR increased by the \( (\hat{m}, \tilde{m}) \)th entry of \( P_{k}(\lambda) \).

Steps 1) through 4) are repeated until the condition given in Step 3 is satisfied.

Basically, FC/MH-CDMA finds a hopping pattern \( P_{k}(\lambda = \lambda_{0}) \) that achieves a smaller BER, and the hopping pattern \( P_{k}(\lambda_{0}) \) is modified to \( P_{k}'(\lambda_{0}) \) by the proposed algorithm, which achieves the target value \( \text{PAR} \), of the PAR at the cost of increasing the BER. However, \( P_{k}'(\lambda_{0}) \) is fed back to the transmitter at the \( \lambda = \lambda_{0} \)th round of feedback, and \( P_{k}'(\lambda_{0}) \) is modified to \( P_{k}(\lambda_{0} + 1) \), which achieves a smaller BER at the cost of increasing the PAR, at the receiver in FC/MH-CDMA. \( P_{k}(\lambda_{0} + 1) \) is modified to \( P_{k}'(\lambda_{0} + 1) \) by the proposed algorithm, which achieves the target value \( \text{PAR} \), at the cost of increasing the BER and is fed back again to the transmitter. By repeating the above process, the proposed algorithm controls the PAR to a preset target value while retaining good BER performance in FC/MH-CDMA.

3.2 Quantization

In order to reduce the amount of feedback information on the hopping pattern \( P_{k}(\lambda) \), we discuss the required number of quantization bits.

Let \( a_{k}^{\text{max}}(\lambda) \) be the maximum absolute value of the real and imaginary parts in all elements of the hopping pattern \( P_{k}'(\lambda) = \{ p'_{k,l,m}(\lambda) \} \) obtained using the PAR control algorithm, that is,

\[ a_{k}^{\text{max}}(\lambda) = \max_{l,m} (|\text{Re}(p'_{k,l,m}(\lambda))|, |\text{Im}(p'_{k,l,m}(\lambda))|). \]

The elements \( p'_{k,l,m}(\lambda) \) of a quantized hopping pattern \( P_{k}'(\lambda) = \{ p'_{k,l,m}(\lambda) \} \) are given by

\[ p'_{k,l,m}(\lambda) = \frac{d_{k}^{\text{max}}(\lambda)}{2^{q-1}} \left[ \frac{p_{k,l,m}(\lambda)}{d_{k}^{\text{max}}(\lambda)} \right]_{\text{round}}, \]

where \([\cdot]_{\text{round}}\) denotes rounding to the nearest integer of the operand, and \((q+1)\) is the number of bits required to quantize each of the real and imaginary parts in all elements of \( P_{k}'(\lambda) \). This is referred to as midtread-type uniform quantization. Therefore, \(2(q+1)LM\) bits are required for the feedback for each quantized hopping pattern.

4. Performance Evaluation

4.1 Specifications

4.1.1 Multipath Model

We assume a six-path model (i.e., \( I_{1} = 6 \) for all \( k \)) that has a delay profile of exponential decay, where the relative intensities of \( |h_{k,i}| \) are 20 log10 \((|h_{k,i+1}|/|h_{k,i}|) = -3 \text{dB} \) \((i = 1, 2, \cdots, I_{k} - 1)\), the path delays \( t_{k,i} \) are \( t_{k,i+1} - t_{k,i} = \frac{L+1}{10} T_{e} \) \((\approx \frac{1}{10} T_{e} \text{ for } L = 7)\), and \( t_{k,i} \) and \( h_{k,i} \) (for all \( k \) and \( i \)) are mutually statistically independent, uniformly distributed random variables in the intervals of \([0, T_{e}]\) and \([0, 2\pi]\), respectively.

In addition to this exponential delay profile, we also employ a six-path uniform delay profile \(20 \text{log}_{10}(|h_{k,i+1}|/|h_{k,i}|) = 0 \text{ dB} \) \((i = 1, 2, \cdots, I_{k} - 1)\) only in Sect. 4.2.3.

4.1.2 Other Specifications

FC/MH-CDMA requires an initial training period during which the receiver returns part of the filter weights, \( P_{k}(\lambda) \), or its altered version, \( P_{k}'(\lambda) \), to the corresponding transmitter. In this paper, we define the initial training period as \( t < (N_{f} + 1) T_{e} + \Delta_{t} + t_{k,1} \) and discuss the BER performance in the steady period, which is defined as the period after the initial training period, that is, \( t \geq (N_{f} + 1) T_{e} + \Delta_{t} + t_{k,1} \). In the initial training period, the PAR control algorithm and quantization are applied to \( P_{k}(\lambda) \) just prior to when the receiver returns the hopping pattern to the transmitter. In the steady period, only the filter weights are updated at the receiver (i.e., no feedback). We assume that the reference \( b_{k}(n) \) used for updating the filter weights is \( b_{k}(n) = b_{k}(n) \) during the initial training period, which implies that the receiver has prior knowledge of the pilot data symbols used for the initial training. Since both the BER and the PAR depend slightly on the randomly chosen values of \( t_{k,1} \) and \( t_{k,i} \), all of the plots are of the average of ten simulation trials. Other common specifications are listed in Table 1.

4.2 Simulation Settings

4.2.1 Parameter Settings

First we discuss the convergence characteristic of the weight

Fig. 4  Ensemble average of squared error $|e_k(n)|^2$ ($K = 32$ and $\mu = 0.1$).

Fig. 5  PAR vs. $\beta$ ($\rho = 0.9$ and $K = 32$).

Fig. 6  PAR vs. $\rho$ ($\beta = 0.3$ and $K = 32$).

matrix (11) updated by the N-LMS algorithm using the step size parameter $\mu = 0.1$ listed in Table 1. Figure 4 shows the characteristic of the ensemble average $E[|e_k(n)|^2]$ of the squared error $|e_k(n)|^2$ vs the time index $n$ of the symbol interval $T_s$, where the number of active signals, $K$, was chosen to be 32. It is observed from Fig. 4 that $10^4$ iterations are sufficient for the adaptation of the weight matrix when $\mu = 0.1$. Therefore, we choose the value of $T_f$ to be $10^4 T_s$, during which the N-LMS adaptation can be sufficiently accomplished and the receiver can be made ready for the feedback.

Next, the proposed PAR control algorithm is verified to effectively control the PAR of the signature waveform $c_k(t)$. Since the PAR control algorithm has two design parameters $\beta$ and $\rho$ in addition to the target value $\text{PAR}_t$, we first set these parameters appropriately. Again, since the PAR control algorithm repeats Steps 1) through 4), as shown in Fig. 3, we also investigate the computational complexity in
Fig. 7 Average loop count for the PAR control algorithm required to reconstruct $P'_k(\lambda)$ from $P_k(\lambda)$ obtained at $t = \lambda T_f + \Delta_k + \alpha T_c + \tau_k$ ($K = 32$).

Figure 5 shows the characteristic of PAR vs. PARc for different values of $\beta$, where $K$ was chosen to be 32. Note that, in Fig. 5, the term average largest PAR denotes the largest value of the PAR among the $K$ ($= 32$) waveforms $c_k(t)$ using $P'_k(\lambda = 10)$, averaged by ten simulations, obtained after the initial training period. The factor $\rho$ was chosen to be 0.9. Figure 5 shows that if $\beta \leq 0.3$, then the values of the PAR obtained are widely fit to the preset values of the target PAR except for PARc < 1 dB.

Figure 6 shows the characteristics of the average largest PAR vs. PARc for different values of $\rho$ with normalized threshold $\beta = 0.3$ and $K = 32$. Figure 6 indicates that if $\rho \geq 0.8$, then the average largest PAR coincides with the preset value of the target PAR, except for PARc < 1 dB. It is observed from Fig. 6 that the average largest PAR increases with decreasing PARc for small values of $\rho$ such as $\rho = 0.1$. For small values of PARc, the PAR control algorithm is completed for most cases when the condition “$N_l \leq 1$ for all $l$” in Step 3) has been satisfied. Since this condition is rapidly satisfied through the coarse operation in Step 4) when the value of $\rho$ is small, the resultant value of the PAR becomes large for small values of PARc in the case of a small value of $\rho$. Note that for a certain desired value of the PAR, the

Fig. 9 Effect of multiple access ($\beta = 0.3$ and $\rho = 0.8$).
FC/MH-CDMA at a common transmission rate. It is known that the value of the PAR of single-carrier QPSK transmission using the root-raised-cosine-filtered pulses is 3 dB or more for a roll-off factor greater than around 0.4, and is 6 dB or more for a roll-off factor of zero [17]. Since 2D SC-CDMA requires a CP-GI, which lengthens the duration of the transmitted signal, its transmission rate becomes slightly low.

Figure 9(a) indicates that when the number of active signals, $K$, is large, the proposed PAR control algorithm slightly deteriorates the BER of FC/MH-CDMA if $\text{PAR}_t = 1 \text{ dB or 3 dB}$. On the other hand, if $\text{PAR}_t = 6 \text{ dB or 9 dB}$, the BER is almost identical to that without the proposed PAR control. Figure 9(b) shows the characteristics of both the average largest PAR and the average PAR as functions of $K$. Figure 9(b) indicates that the PAR control algorithm works well independent of $K$.

4.2.3 Effect of Quantization

We investigate the relationship between the PAR and $q$ (the number of quantizing bits per real or imaginary part per chip per frequency). Here, we assume the midtread-type uniform quantization described in Sect. 3.2.

Figure 10 shows the average largest PAR vs. PAR$_t$ for $K = 32$. The figure shows that the PAR performance for the case in which $q \geq 6$ is almost identical to that for the case...
with no quantization.

The characteristics of the BER vs. $E_b/N_0$ for $K = 32$ and $q = 6$ bits are shown in Fig. 11(a), and the complementary cumulative distribution functions (CCDFs), $Pr(\text{PAR} > \text{PAR}_0)$, of the PAR for $P^f(\lambda = 10)$ (without quantization) and $P^q(\lambda = 10)$ (with quantization) using 320 hopping patterns obtained through ten simulation trials for $K = 32$, $q = 6$ bits, and $E_b/N_0 = 9.6$ dB are shown in Fig. 11(b). Figure 11(a) indicates that the proposed algorithm achieves sufficient BER performance even when $\text{PAR} = 1$ dB or 3 dB. Again, Fig. 11(b) indicates that the PAR becomes slightly large with quantization for the hopping patterns.

So far we have considered a six-path channel model that has an exponential delay profile. Finally, we consider a six-path channel model that has a uniform delay profile. Figures 12(a) and 12(b) show the characteristics of the BER vs. $E_b/N_0$ and the CCDFs, in which the same parameters as those in Figs. 11(a) and 11(b) are chosen, except that a uniform delay profile is assumed. The curves for FC/MH-CDMA shown in Fig. 12(a) are shifted to the right by 1.6 dB at a BER of $10^{-4}$ in comparison with those shown in Fig. 11(a) because of the large delay spread of the channel. It is observed from Fig. 12(a) that the proposed PAR control algorithm only slightly deteriorates the BER of FC/MH-CDMA independent of the channel delay profile. It is also verified from Fig. 12(b) that CCDF characteristics similar to those shown in Fig. 11(b) are obtained independent of the channel delay profile.

Note that the asynchronous multiple-access performance is considered in multipath environments for all of the results except for the case in which synchronous 2D SC-CDMA is considered.

5. Conclusion

A PAR control algorithm for asynchronous FC/MH-CDMA signals was proposed, and the relationship between the PAR and the BER was shown over a time-invariant multipath channel. The effect of the quantization was investigated, and it was demonstrated that time-frequency hopping patterns that achieve small values of the target PAR can be constructed using the proposed algorithm. The BER was also shown to have little effect if the target PAR is larger than 3 dB.

The proposed PAR control algorithm is directly applicable to autonomous, decentralized, multiple-access systems.
